Abstract

We investigate the complexity of satisfiability problems that, surprisingly, (to the best of our knowledge) have not yet been considered in the literature.

CNF-SAT, which we also denote by \( \land \lor \)-SAT, asks for an assignment for a given formula that satisfies all of its clauses. While \( \land \lor \)-SAT is NP-complete,

- what is the complexity of \( \oplus \lor \)-SAT, where it is asked for an assignment that satisfies an odd number of clauses?

We show that \( \oplus \lor \)-SAT can be solved by a randomized algorithm in polynomial time. The result is extended to \( \oplus \)-Th-SAT, where we have a threshold instead of an or at the input level.

MaxSAT, which we also denote by Th-\( \lor \)-SAT, is a generalization of CNF-SAT, and hence NP-complete.

- What is the complexity of the analogous optimization version of DNF-SAT, an easy problem, Th-\( \land \)-SAT?

We show that Th-\( \land \)-SAT is NP-complete, and the same holds for Th-\( \oplus \)-SAT, where we have a parity instead of an and at the input level.

1 Introduction

In a seminal paper, Cook [Coo71] showed that the satisfiability problem for Boolean formulas, SAT, is NP-complete. From then on, SAT has been reduced to many other NP problems, thereby showing them to be NP-complete as well (see [GJ79] for a good introduction to NP completeness). In order to facilitate such reductions it has been useful to have the Boolean formulas in certain normal forms or to have certain properties. We give some examples. Most notably, the satisfiability problem for formulas in conjunction normal form, CNF-SAT, or even with the restriction to at most 3 literals per clause, 3-CNF-SAT, is NP-complete. Other variants

*Research done while visiting the university of Ulm, Germany. Supported in part by an Alexander von Humboldt fellowship.

are based on 3-CNF-SAT are: Not-All-Equal-SAT [Schaefer78], where it is asked for a satisfying assignment of a given 3-CNF formula, that, for any clause, doesn’t set all 3 literals to 1. In One-In-Three-SAT [Schaefer78], for any clause, exactly one literal should be 1. More general, Not-All-Equal-SAT and One-In-Three-SAT are just special cases of the class of generalized satisfiability problems introduced by Schaefer [Schaefer78] (see also [GJ79], p. 260). Schaefer gives a dichotomy theorem to classify all the properties one can impose on assignments as in the examples above such that the satisfiability problem is still \( \text{NP} \)-complete. An analogous theorem for the corresponding counting problems was recently shown in [CH96].

On the other hand, for certain other restrictions, the satisfiability problem becomes easy: for example for Horn formulas it is solvable in polynomial time, \( \text{P} \) (in fact, it is \( \text{P} \)-complete). 2-CNF-SAT, where there are at most 2 literals per clause, can be solved nondeterministically in logarithmic space, \( \text{NL} \) (in fact, it is \( \text{NL} \)-complete). The satisfiability problem for formulas in disjunctive normal form, \( \text{DNF-SAT} \), can even be solved in logarithmic space, \( \text{L} \).

\( \text{CNF-SAT} \) asks for an assignment satisfying all of the clauses of a given formula. If not all clauses can be satisfied, the next interesting question is how many clauses can be simultaneously satisfied at maximum. The question of how well this optimization problem can be approximated has attracted much interest due to the new results on probabilistically checkable proofs (PCP). The associated decision version, \( \text{MaxSAT} \), has as input a CNF formula \( F \) and a number \( k \); we are then asked whether there is some assignment satisfying at least \( k \) clauses of \( F \). It is clear that \( \text{MaxSAT} \) is as least as difficult as \( \text{CNF-SAT} \), and hence is \( \text{NP} \)-complete. An interesting point however is that the \( \text{MaxSAT} \) problem for 2-CNF-SAT, call it 2-MaxSAT, is \( \text{NP} \)-complete as well, even though 2-CNF-SAT is in \( \text{P} \) [GJS76] (see also [Pap94], Theorem 9.2).

The switch from \( \text{CNF-SAT} \) to \( \text{MaxSAT} \) can also be seen as follows. Adapting terminology from circuit theory, we call a CNF formula also a \( \land \)-over-\( \lor \) formula, or having an \( \land \)-gate over an \( \lor \)-gate. Correspondingly, \( \text{CNF-SAT} \) is also denoted by \( \land \lor \text{-SAT} \). Now consider \( \text{MaxSAT} \). This is obtained from \( \land \lor \text{-SAT} \) by exchanging the \( \land \)-gate at the output by a threshold-gate, i.e., \( \text{MaxSAT} = \text{Th} \lor \text{-SAT} \).

Let us now analogously replace the \( \lor \)-gate of DNF formulas by a threshold-gate. That is, we ask for the complexity of \( \text{Th} \land \text{-SAT} \). Although we have derived the problem from an easy one, namely \( \text{DNF-SAT} \), we show in Section 3 that \( \text{Th} \land \text{-SAT} \) is \( \text{NP} \)-complete.

In this paper we also consider satisfiability problems where in addition to threshold gates we allow parity gates. For example, replacing the \( \land \)-gate of CNF formulas by a parity-gate, we are asking for assignments satisfying an odd number of clauses of a given formula. In Section 2 we show that \( \land \lor \text{-SAT} \) can be solved by a randomized Las Vegas type algorithm in polynomial time, in symbols: \( \land \lor \text{-SAT} \in \text{RP} \). Our technique is to arithmetize such formulas which leads to multilinear polynomials over \( \text{GF}(2) \). Considering these polynomials in a small extension field, \( \text{GF}(2^4) \), we can then apply the Schwartz-Zippel Theorem to solve the problem by a probabilistic zero test. If one exchanges the remaining \( \lor \)-gate by a more general threshold-gate, an odd number of threshold gates has to be 1 in order to satisfy a parity-over-threshold formula. By extending the algorithm for \( \land \lor \text{-SAT} \), we show that \( \land \text{-Th-SAT} \) is still in \( \text{RP} \). Moreover, our algorithm can be extended to work even for \( \land \text{-Th-SAT} \) with weighted threshold gates. This has a nice interpretation in terms of a integer linear programming problem where it is just required to satisfy an odd number of inequalities instead of all.

Since we are using 4 operations, namely \( \{ \land, \lor, \text{Th}, \oplus \} \), there are 16 ways of building depth two
formulas. However, for most these, the complexity of the corresponding satisfiability problem is easy to see. For example, as for DNF-SAT, having an or at the output level makes the problem trivial. If we take twice the same operation, then clearly \( \land\)-SAT, \( \lor\)-SAT, and \( \land\)-\( \lor\)-SAT are in \( \mathbf{P} \). For Th-Th-SAT, note that and and or are specific threshold operations. Therefore Th-Th-SAT is at least as difficult as CNF-SAT, and hence is \( \mathbf{NP}\)-complete. For the same reason this holds also for Th-\( \lor\)-SAT and \( \land\)-Th-SAT. To keep track for the reader: we classified already 10 of the 16 satisfiability problems in this paragraph.

The complexity of the remaining 6 is not as obvious. We partition them in 2 groups according to the type of operation at the output level. In Section 2 we show that \( \land\)-\( \lor\)-SAT, \( \land\)-\( \lor\)-SAT, and \( \land\)-Th-SAT can be solved by a randomized Las Vegas type algorithm in polynomial time. Therefore these problems are unlikely to be \( \mathbf{NP}\)-complete. In Section 3, we show that \( \land\)-\( \lor\)-SAT can be solved in polynomial time, while Th-\( \land\)-SAT and Th-\( \lor\)-SAT are \( \mathbf{NP}\)-complete.

## 2 Parity at the Output

In CNF-SAT we are seeking for an assignment that satisfies all the clauses of a formula. Replacing the and-gate by a parity-gate, we ask for an assignment that satisfies an odd number of clauses. Note first that one can do complements with parity by adding a 1 to its inputs, namely \( \oplus(x_1, \ldots, x_n) + 1 = \oplus(1, x_1, \ldots, x_n) \). Hence, using de Morgan’s laws, we can transform a parity-over-or formula into an equivalent parity-over-and formula and vice versa. Therefore, \( \land\)-\( \lor\)-SAT is many-one equivalent to \( \land\)-\( \lor\)-SAT. Next observe that we can arithmitize any parity-over-and formula \( F(x_1, \ldots, x_n) \). Namely, \( F \) corresponds to a polynomial \( p_F(x_1, \ldots, x_n) \) over \( \mathbb{F}_2 \), where parity is interpreted as addition and and as multiplication. An occurrence of a variable \( x_i \) in \( F \) is kept as \( x_i \) in \( p_F \), and a negated variable \( \overline{x_i} \) is replaced by \( (1 + x_i) \). Clearly, we have

\[
F \in \land\oplus\land-SAT \iff p_F \neq 0.
\]

**Remark 2.1** \#P [Val79a] is the class of counting problems, where one wants to compute the number of solutions of \( \mathbf{NP} \) problems. For all the known \( \mathbf{NP}\)-complete problems, the corresponding counting version is \#P-complete. This gives rise to the conjecture that if a counting problem is not \#P-complete, then its decision version should not be \( \mathbf{NP}\)-complete. Note however that the counting version of an easy problem can be \#P-complete as well. An example is DNF-SAT [Val79b].

Ehrenfeucht and Karpinski [EK89] have considered the problem of counting the number of zeros of multivariate polynomials over \( \mathbb{F}_2 \), like \( p_F \) from above. They have shown that it is \#P-complete. Hence we cannot conclude anything from this result for the complexity of the decision version.

Polynomial \( p_F \) is given as a sum of terms, where each term is a product of the form \( x_{i_1} \cdots x_{i_k} \cdot (1 + x_{j_1}) \cdots (1 + x_{j_s}) \). In order to test whether \( p_F \) is the zero-polynomial, we can multiply out each term and write \( p_F \) as a sum of monoms. Then \( p_F \) is the zero-polynomial if and only in this process all resulting (intermediate) monoms cancel each other. Note however, that the term above results in \( 2^s \) monoms, so that the above procedure works in polynomial time only for \( l = O(\log |F|) \). In particular, for \( k\)-\( \land\)-\( \lor\)-SAT, where any clause has at most \( k \) literals, we have
Proposition 2.2 \( k\)-\(\oplus\)-\("\land\)-SAT \(\in\) \(\text{P}\), for any \(k > 0\).

In the case that \(l\) is unbounded, no polynomial-time algorithm is known. Below we give a randomized polynomial-time algorithm for \(\oplus\)-\("\land\)-SAT. As a consequence, \(\oplus\)-\("\land\)-SAT is very unlikely to be \(\text{NP}\)-complete.

Schwartz [Schw80] and Zippel [Zip79] give efficient algorithms that probabilistically check whether a multivariate polynomial is all zero. Below, we state a variant of their main theorem for multilinear polynomials that was implicitly shown by Blum, Chandra, and Wegman [BCW80]. An explicit statement, generalized to arbitrary multivariate polynomials can be found in [IM83].

Theorem 2.3 [BCW80, Schw80, Zip79, IM83] Let \(p(x_1, \ldots, x_n)\) be a multilinear polynomial over a field \(\mathbb{F}\) that is not the zero polynomial. Let \(S \subseteq \mathbb{F}\) with \(|S| > 1\). Then there are at least \((|S| - 1)^n\) points \((a_1, \ldots, a_n) \in S^n\) such that \(p(a_1, \ldots, a_n) \neq 0\).

The standard way to apply the theorem for a zero test is quite obvious: fix a large enough subset \(S\) of \(\mathbb{F}\), for example, \(|S| = 2n\). Now, for a randomly chosen point \((r_1, \ldots, r_n) \in S^n\) we have \(p(r_1, \ldots, r_n) \neq 0\) with probability greater than \(((|S| - 1)/|S|)^n = (1 - (1/2n))^n \geq 1/2\), when \(p \neq 0\).

However, we cannot directly apply the theorem that way in our case because, for \(\mathbb{F} = \text{GF}(2)\), there are just 2 elements in \(\mathbb{F}\). The trick now is to work in a small extension field of \(\text{GF}(2)\) instead. This method is mentioned by Ibarra and Moran [IM83] and also used for example by Grigoriev et al. [GKS90] in a slightly different setting (to interpolate sparse polynomials).

Theorem 2.4 \(\oplus\)-\("\land\)-SAT \(\in\) \(\text{RP}\).

Proof. Let \(F(x_1, \ldots, x_n)\) be a \(\oplus\)-\("\land\)-SAT formula and let \(p_F(x_1, \ldots, x_n)\) be the corresponding polynomial over \(\text{GF}(2)\) as defined above. Note that \(p_F\) is multilinear. Define \(s = \lceil \log 2n \rceil\) and consider \(\text{GF}(2^s)\). Let \(\hat{p}_F(x_1, \ldots, x_n)\) denote the extension of \(p_F\) over \(\text{GF}(2^s)\), so that \(\hat{p}_F\) and \(p_F\) agree on \(\text{GF}(2^n)\). Suppose \(\hat{p}_F\) is not the zero polynomial. Applying Theorem 2.3 with \(S = \text{GF}(2)\), we get that \(\hat{p}_F\), and hence \(p_F\), have a nonzero point in \(\text{GF}(2)\). Hence we can conclude that \(p_F\) is the zero polynomial over \(\text{GF}(2)\) if and only if \(\hat{p}_F\) is the zero polynomial over \(\text{GF}(2^s)\).

In order to evaluate \(\hat{p}_F\) at a point in \(\text{GF}(2^s)\), we need an irreducible polynomial \(\phi(x) \in \text{GF}(2)[x]\) of degree \(s\). (See for example [vdWae70] for background.) Then \(\text{GF}(2^s)\) is isomorphic to \(\text{GF}(2)[x]/\phi(x)\). Note that there are only \(2^{s+1} = 4n\) polynomials of degree \(s\) in \(\text{GF}(2)[x]\). Berlekamp [Ber70] showed that irreducibility of a polynomial can be checked in polynomial time. Therefore, by cycling through all possible polynomials, one can find an irreducible one in polynomial time.

Now we can apply Theorem 2.3 with \(S = \text{GF}(2^s)\). If \(\hat{p}_F\) is not the zero polynomial, we will detect it with probability greater than \(1/2\). \(\Box\)

Next we consider \(\oplus\)-Th-SAT which is a generalization of the just solved \(\oplus\)-\("\land\)-SAT problem. That is, in each clause, there has to be achieved a certain threshold value of 1’s for the clause to be true. The question is whether there is an assignment satisfying an odd number of threshold clauses.
The first idea might be to try a similar approach as for \( \oplus \land \text{-SAT} \), where we interpreted a parity-over-and formula as a (compactly written) polynomial over GF(2). The important point was that we could efficiently evaluate such a polynomial at any given point in an appropriate extension field. However, in the case of a parity-over-threshold formula we do not even have such a compact description of the polynomial. Again it is easy to see that the straightforward method of transforming the formula into a polynomial as a sum of monomials might lead to exponentially many (intermediate) monoms: consider a threshold formula \( F = \text{Th}_k^n(x_1, \ldots, x_n) \) that evaluates to 1 if at least \( k \) of its \( n \) inputs are 1’s. The corresponding polynomial \( p_F \) over GF(2) has the following form.

\[
p_F = \sum_{i=k}^{n} \sum_{S \subseteq \{1, \ldots, n\} \mid |S|=i} \prod_{s \in S} x_s \prod_{t \in S^c} (x_t + 1).
\]

Hence \( p_F \) consists of \( \sum_{i=0}^{n-k} \binom{n}{i} \) monoms, each consisting of \( n \) terms of the form \( x_j \) or \( 1 + x_j \).

We conclude that we can handle \( p_F \) efficiently if \( n - k \) is constant. Since we are dealing with parity-over-threshold formulas, we can use the parity for negation. Hence, a similar argument as above works when the threshold \( k \) is bounded by a constant. In particular, we have an efficient algorithm if the fan-in of the threshold gate is bounded.

**Proposition 2.5** \( k \oplus \text{-Th-SAT} \in \mathbf{P} \), for any \( k > 0 \).

In the general case, the crucial observation is that we can evaluate the polynomial associated with a parity-over-threshold formula \( F \) without having a compact explicit way of writing it: \( F \) itself can be used to evaluate \( p_F \) by dynamic programming. Then we can continue as in the proof of Theorem 2.4.

**Theorem 2.6** \( \oplus \text{-Th-SAT} \in \mathbf{RP} \).

**Proof.** Consider the threshold formula \( \text{Th}_k^n(x_1, \ldots, x_n) \) that evaluates to 1 if at least \( k \) of its \( n \) inputs are 1’s. Let \( t_k^n(x_1, \ldots, x_n) \) be the polynomial over GF(2) that represents \( \text{Th}_k^n \). We have the following recurrence relation for \( 1 \leq k < n \).

\[
t_k^n(x_1, \ldots, x_n) = x_n \cdot t_{k-1}^{n-1}(x_1, \ldots, x_{n-1}) + (1 - x_n) \cdot t_k^{n-1}(x_1, \ldots, x_{n-1}).
\]

The base cases are \( t_l^n(x_1, \ldots, x_l) = x_1 \cdots x_l \) and \( t_0^n(x_1, \ldots, x_l) = 1 \), for \( l = 1, \ldots, n \). Therefore, to evaluate \( t_k^n \) over GF(2) at a given point, we can use dynamic programming: we simply have to fill out a table with at most \( n(k + 1) = O(n^2) \) entries.

Now, let \( F(x_1, \ldots, x_n) \) be a parity-over-threshold formula having \( m \) threshold clauses. We can write the polynomial \( p_F \) representing \( F \) over GF(2) as follows.

\[
p_F(x_1, \ldots, x_n) = \sum_{i=1}^{m} t_{k_i}^{n_i},
\]

where each polynomial \( t_{k_i}^{n_i} \) has some \( n_i \) literals as input. We can evaluate \( p_F \) over GF(2) at a given point by evaluating each of the \( t_{k_i}^{n_i} \) as described above and then adding up all the values obtained. Now we can proceed as in Theorem 2.4. \( \square \)
The base cases are \( w^t \) and prime power, the complexity of \( \text{Mod}(m)\)-\( \text{Th-SAT} \) is in \( \text{RNC} \). For \( \oplus\)-\( \land\)-\( \text{SAT} \) this is immediate from our algorithm (note that testing irreducibility in small fields is in \( \text{NC}^2 \)). For \( \oplus\)-\( \text{Th-SAT} \), there is a dynamic programming step which might not be parallelizable. However, in our case, the specific table we have to fill out according to equation (1) can be seen as an arithmetic circuit of degree \( n \) over \( \text{GF}(2) \). Miller, Ramachandran, and Kaltofen [MRK88] have shown that such circuits can be evaluated in \( \text{NC}^2 \).

Remark 2.8 When we take modulo \( m \) gates instead of parity gates, all we need for the above algorithms to work correctly is that the formulas have some associated polynomial over some field. Therefore, we have \( \text{Mod}(m)\)-\( \text{Th-SAT} \in \text{RP} \) for any prime power \( m \). For \( m \) not being a prime power, the complexity of \( \text{Mod}(m)\)-\( \oplus\)-\( \land\)-\( \text{SAT} \) and \( \text{Mod}(m)\)-\( \text{Th-SAT} \) remains open.

Finally, we show that Theorem 2.6 can be generalized to weighted threshold gates with polynomially bounded weights. This yields a randomized algorithm to solve the parity version of Integer Linear Programming in polynomial time.

Consider a weighted threshold gate

\[
 w_1 x_1 + \cdots + w_n x_n \geq k,
\]

where \( w_1, \ldots, w_n \) are integer weights. Let \( wt_k^n(x_1, \ldots, x_n) \) be the polynomial over \( \text{GF}(2) \) that represents the weighted threshold gate. Observe that we still have a recurrence relation analogous to equation (1). Namely, let \( N \) be the sum of the negative weights and \( P \) be the sum of the positive weights. For \( N < k < P \)

\[
 wt_k^n(x_1, \ldots, x_n) = x_n \cdot wt_{k-w_n}^{n-1}(x_1, \ldots, x_{n-1}) + (1 - x_n) \cdot wt_{k}^{n-1}(x_1, \ldots, x_{n-1}).
\]

The base cases are \( wt_k^p(x_1, \ldots, x_n) = y_1 \cdots y_m \), where \( y_i = x_i \) if \( w_i > 0 \), and \( y_i = 1 - x_i \) otherwise, and \( wt_N^N(x_1, \ldots, x_n) = 1 \). Let \( W = N + P = \|(w_1, \ldots, w_n)\|_1 \). To evaluate \( t_k^n \) over \( \text{GF}(2) \) we have to fill out a table with at most \( O(nW) \) entries. This can be done in polynomial time when \( W \) is polynomially bounded. It follows that \( \oplus\)-\( \text{Th-SAT} \) is in \( \text{RP} \) even with polynomially bounded threshold gates.

Now consider the Integer Linear Programming problem, ILP: given a \( m \times n \) matrix \( A \) and a \( m \) vector \( b \), is there a \( n \) vector \( x \) such that \( Ax \geq b \), where \( A, b, \) and \( x \) are over the integers? ILP, and even 0-1-ILP, where \( x \) is required to be a zero-one vector, is \( \text{NP} \)-complete [Kar72]. For 0-1-ILP, note that each row in \( Ax \geq b \) can be seen as a weighted threshold gate as above. By the preceding discussion we conclude that the parity version of 0-1-ILP, call it odd-0-1-ILP, that asks for a zero-one vector \( x \) such that an odd number of the conditions is satisfied, is in \( \text{RP} \).

Corollary 2.9 odd-0-1-ILP with polynomially bounded weights is in \( \text{RP} \).

Clearly, Remark 2.7 and 2.8 apply to weighted \( \oplus\)-\( \text{Th-SAT} \) and odd-0-1-ILP as well.
3 Threshold at the Output

We start by considering $\land \oplus$-SAT. Given a $\land$-over-parity formula $F$, we are seeking for an assignment such that in all the parity clauses an odd number of literals has value one. This can be seen as a set of linear equations over $GF(2)$ that have to be satisfied simultaneously. Therefore $\land \oplus$-SAT can be solved in polynomial time, in fact in $NC^2$.

**Proposition 3.1** $\land \oplus$-SAT ∈ $P$.

**Remark 3.2** The approach via linear equations over $GF(2)$ gives not only an efficient way to decide $\land \oplus$-SAT but even to count the number of solutions in polynomial time. This contrasts with the fact that the counting version of DNF-SAT is $\#P$-complete [Val79].

Next we generalize to threshold-over-parity formulas. In the above setting of linear equations, we ask, for some threshold value $k$, whether some $k$-subset of the equations is simultaneously satisfiable. In contrast to the case where all equations have to be fulfilled, there is no polynomial-time algorithm known for this generalization. We show below that the problem is in fact $NP$-complete. Before doing so, we argue that the problem is easy for certain threshold values $k$ that depend on the number of clauses a formula has.

Consider a formula $F \in \text{Th-} \oplus$-SAT and assume that no constants are fed into the threshold gate. We make a random assignment to the variables, that is, each variable is assigned independently a value 0 or 1 with equal probability. Then we expect a variable to have value 1 with probability 1/2. Also, for a clause $C = l_1 \oplus \cdots \oplus l_k$, we have $E(C \text{ evaluates to } 1) = 1/2$. Because of the linearity of the expectation, a random assignment is expected to satisfy 1/2 of the clauses. Therefore there also exist such an assignment. We conclude that the problem is trivial for thresholds up to 1/2. However, $\text{Th-} \oplus$-SAT is $NP$-complete for thresholds (strictly) between 1/2 and 1.

**Theorem 3.3** $\text{Th-} \oplus$-SAT is $NP$-complete.

**Proof.** We reduce 3-CNF-SAT to $\text{Th-} \oplus$-SAT. Consider a clause $C = l_1 \lor l_2 \lor l_3$ of a given 3-CNF formula $F$, for literals $l_1, l_2, l_3$. From $C$ we define the following sequence of 7 formulas

$$S(C) = (l_1, l_2, l_3, l_1 \oplus l_2, l_1 \oplus l_3, l_2 \oplus l_3, l_1 \oplus l_2 \oplus l_3).$$

Let $a$ be an assignment to the literals. Observe that when $a$ does not satisfy $C$, then none of the formulas of $S(C)$ is satisfied. On the other hand, if $a$ satisfies $C$, then exactly four formulas of $S(C)$ are satisfied, no matter which of the literals of $C$ are satisfied by $a$.

Let formula $F$ have $m$ clauses. We construct a threshold-over-parity formula $G$ as follows: for each clause $C$ of $F$, we put all formulas from $S(C)$ as input to the threshold-gate of $G$ which therefore has fan-in $7m$. It follows that if an assignment $a$ satisfies $F$, then exactly $4m$ inputs of the threshold-gate are on when $a$ is given as input to $G$. If $a$ does not satisfy $F$, then at most $4(m-1)$ inputs of the threshold-gate are on.

Thus, with a $4m$ threshold-gate on top, $G$ is satisfiable if and only if $F$ is satisfiable. In fact, by the above discussion, we could even use a $4m$ equality-gate. \qed
Remark 3.4 If we use modulo $m$ gates instead of parity gates, note first that Th-Mod$(m)$-SAT is clearly NP-complete for $m > 3$, since in that case, the modulo $m$-gate behaves like an or-gate on clauses with 3 literals. So the only interesting case that remains is when $m = 3$: for a clause $C$ consisting of the literals $l_1, l_2, l_3$, we consider the following sequence of 15 formulas.

$$S(C) = ( l_1, l_2, l_3, \ \\
\phantom{S(C) = (} l_1, l_2, l_3, \ \\
\phantom{S(C) = (} 2l_1 + l_2, 2l_1 + l_3, 2l_2 + l_3, \ \\
\phantom{S(C) = (} 2l_1 + l_2, 2l_1 + l_3, 2l_2 + l_3, \ \\
\phantom{S(C) = (} 2l_1 + l_2 + l_3, l_1 + 2l_2 + l_3, l_1 + l_2 + 2l_3),$$

where $+$ denotes addition in GF(3), i.e., according to the modulo 3-gate. Now, if clause $C$ is not satisfied by an assignment, then none of the formulas of $S(C)$ have value 1. On the other hand, if an assignment satisfies $C$, then exactly 9 formulas from $S(C)$ have value 1. Then we can continue in the same way as in the proof of Theorem 3.3. It follows that Th-Mod$(3)$-SAT is NP-complete.

Note that this result also follows from the NP-completeness of 2-MaxSAT [GJS76], because again, a modulo 3-gate works like an or-gate on clauses with 2 literals.

Finally, we consider the satisfiability problem when the or-gate of a DNF formula is replaced by a threshold-gate. Although DNF-SAT can be solved in logarithmic space, Th-$\wedge$-SAT is again a hard problem.

Theorem 3.5 Th-$\wedge$-SAT is NP-complete.

Proof. We reduce 3-CNF-SAT to Th-$\wedge$-SAT. Consider a clause $C = l_1 \lor l_2 \lor l_3$ of a given 3-CNF formula $F$, for literals $l_1, l_2, l_3$. There are seven assignments that satisfy $C$: if assignment $a$ satisfies $C$, then $a$ satisfies exactly one of the following formula from the following sequence.

$$S(C) = ( l_1 \land l_2 \land l_3, \ \\
\phantom{S(C) = (} \bar{l}_1 \land l_2 \land l_3, l_1 \land \bar{l}_2 \land l_3, l_1 \land l_2 \land \bar{l}_3, \ \\
\phantom{S(C) = (} \bar{l}_1 \land \bar{l}_2 \land l_3, \bar{l}_1 \land l_2 \land \bar{l}_3, \bar{l}_1 \land \bar{l}_2 \land \bar{l}_3).$$

Let formula $F$ have $m$ clauses. To construct a threshold-over-And formula $G$, take a threshold-gate with fan-in $7m$. We put, for each clause $C$ of $F$, the corresponding seven formulas $S(C)$ as inputs to the threshold-gate. It follows that if an assignment $a$ satisfies $F$, then exactly $m$ inputs of the threshold-gate are on when $a$ is given as input to $G$. If $a$ does not satisfy $F$, then at most $m - 1$ inputs of the threshold-gate are on.

Thus, with a $m$ threshold- (or equality-) gate on top, $G$ is satisfiable if and only if $F$ is satisfiable.

4 Open Problems

What is the complexity of Mod$(m)$-$\wedge$-SAT and Mod$(m)$-Th-SAT, when $m$ is not a prime power?
Acknowledgments

We want to thank V Vinay, who originated this research by asking for the complexity of $\oplus - \forall - \text{SAT}$. Discussions with Lance Fortnow yielded Proposition 2.2 as a first step. He also helped in Theorem 2.6. Finally, we want to thank Marek Karpinski for very useful hints to the literature, and Jin-yi Cai for helpful discussions.
