Kane prosal

A silicon-based nuclear spin quantum computer

B. E. Kane

Semiconductor Nanofabrication Facility, School of Physics, University of New South Wales, Sydney 2052, Australia

Quantum computers promise to exceed the computational efficiency of ordinary classical machines because quantum algorithms allow the execution of certain tasks in fewer steps. But practical implementation of these machines poses a formidable challenge. Here I present a scheme for implementing a quantum-mechanical computer. Information is encoded onto the nuclear spins of donor atoms in doped silicon electronic devices. Logical operations on individual spins are performed using externally applied electric fields, and spin measurements are made using currents of spin-polarized electrons. The realization of such a computer is dependent on future refinements of conventional silicon electronics.

Although the concept of information underlying all modern computer technology is essentially classical, phsyicists know that nature obeys the laws of quantum mechanics. The idea of a quantum computer has been developed theoretically over several decades to elucidate fundamental questions concerning the capabilities and limitations of machines in which information is treated quantum to quantum computation[11,12] circumvents the single-spin detection problem essentially by performing quantum calculations in parallel in a large number of molecules and determining the result from macroscopic magnetization measurements. The measurable signal decreases with the number of qubits, however, and scaling this approach above about ten qubits will be technically demanding[37]
Kane scheme

Figure 1 Illustration of two cells in a one-dimensional array containing ^{31}P donors and electrons in a Si host, separated by a barrier from metal gates on the surface. 'A gates' control the resonance frequency of the nuclear spin qubits; 'J gates' control the electron-mediated coupling between adjacent nuclear spins. The ledge over which the gates cross localizes the gate electric field in the vicinity of the donors.
Figure 2 An electric field applied to an A gate pulls the electron wavefunction away from the donor and towards the barrier, reducing the hyperfine interaction and the resonance frequency of the nucleus. The donor nucleus-electron system is a voltage-controlled oscillator with a tuning parameter α of the order of 30 MHz V^{-1}.

Motivation: Solid state QC with quantum dots (Kane proposal)
Control of strength of hyperfine interaction
⇨ Voltage controlled oscillator

Switch on/off: Electron mediated coupling between nuclear spins

B_{ac} flips nuclear spins at resonance

Readout:
  nuclear spin
⇨ electron spin
⇨ orbital wavefunction
⇨ capacitance meas.

Multipartite Entanglement Among Single Spins in Diamond

P. Neumann,[1]* N. Mizuochi,[2]* F. Rempp,[1] P. Hemmer,[3] H. Watanabe,[4] S. Yamasaki,[5] V. Jacques,[1] T. Gaebel,[1] F. Jelezko,[1] J. Wrachtrup[1]†

Robust entanglement at room temperature is a necessary requirement for practical applications in quantum technology. We demonstrate the creation of bipartite- and tripartite-entangled quantum states in a small quantum register consisting of individual ¹³C nuclei in a diamond lattice. Individual nuclear spins are controlled via their hyperfine coupling to a single electron at a nitrogen-vacancy defect center. Quantum correlations are of high quality and persist on a millisecond time scale even at room temperature, which is adequate for sophisticated quantum operations.

Fig. 1. (**A**) Atomic structure of the NV center. The nitrogen atom, vacancy, and three nearest-neighbor carbon atoms are shown. Two of the carbon atoms are ¹³C isotopes with nuclear spin 1/2. (**B**) Energy-level scheme of electronic ground state of the NV center. Two of three hyperfine split electron spin sublevels (mₛ = 0,−1) are depicted. Allowed transitions are shown by solid arrows (blue, electron spins; orange, nuclear spins). Zero and double quantum transitions are shown as dashed arrows. For further information, see (15). (**C**) ODMR spectrum (red curve) showing the mₛ = 0↔−1 transition. The simulated spectrum (blue curve) accounts for the hyperfine splitting of a single electron spin with two nearest-neighbor ¹³C atoms. a.u., arbitrary units.

Table 1. Fidelity and entanglement measures for Bell, *GHZ*, and *W* states. Dashes indicate that the respective coherence measures were not calculated.

| Coherence measure → Bell state ↓	Fidelity	Concurrence	Partial transpose
Ψ⁺	0.80 ± 0.07	0.65⁺⁰·¹⁵₋₀.₀₈	−0.31⁺⁰·⁰⁵₋₀.₀₆
Ψ⁻	0.81 ± 0.06	0.59 ± 0.11	−0.32⁺⁰·⁰⁴₋₀.₀₅
Φ⁺	0.98 ± 0.05	0.96⁺⁰·⁰⁴₋₀.₀₉	−0.49⁺⁰·⁰⁴₋₀.₀₂
Φ⁻	0.96 ± 0.05	0.92⁺⁰·⁰⁷₋₀.₀₈	−0.47 ± 0.46
GHZ	0.87 ± 0.06	—	—
W	0.85⁺⁰·⁰⁵₋₀.₁	—	—

Fig. 2. (**A**) Pulse sequence for Bell state generation (Φ⁻) among two nuclear spins. Spin-selective pulses are represented by squares, operating on a target qubit. Vertical lines represent logical connections. The control qubit state |1⟩ and the state |0⟩ are displayed as closed and open circles, respectively. For example, an open circle indicates that the pulse is applied to the target qubit if the quantum state of the controlling qubit is |0⟩. Bell states evolve during time τ followed by state tomography. During six different transfer steps, the six possible coherences among the four nuclear spin states are unitarily mapped onto nuclear spin N₁. Each coherence is completely analyzed by performing two nutations (nut.) with two 90° phase-shifted rf fields. The results are the density matrix elements. (**B**) Ramsey fringes of Bell states: (i) Φ⁺, (ii) Φ⁺ and Φ⁻, (iii) Ψ⁺, and (iv) Ψ⁺ and Ψ⁻. The frequency offsets of rf1 (Δω₁), rf2 (Δω₂), and fitted curve (ω_fit) are: (i) Δω₁ = 0.5, Δω₂ = 0.5, and ω_fit = 1.0 MHz ≈ Δω₁+Δω₂; (ii) Δω₁ = 0, Δω₂ = 0.5, and ω_fit = 0.5 MHz ≈ Δω₁+Δω₂; (iii) Δω₁ = −0.3, Δω₂ = 1.0, and ω_fit = 1.3 MHz ≈ Δω₂−Δω₁; and (iv) Δω₁ = 0, Δω₂ = 0.4, and ω_fit = 0.4 MHz ≈ Δω₂−Δω₁. (**C**) Density matrix reconstruction (real part) of states Φ⁻ and Ψ⁺. Imaginary parts are found in (15). The high absolute values of the main off-diagonal elements (Φ⁻: |00⟩⟨11|, |11⟩⟨00|; Ψ⁺: |10⟩⟨01|, |01⟩⟨10|) prove that these are, in fact, entangled states and not just incoherent mixtures (otherwise, all off-diagonal elements would be zero). (**D**) Coherence time of Bell states as compared with the relaxation time of the electron T₁.

Rabi Oszill.

Figure 4.18: Coherent oscillations measured on sample `Hyp30S` using a drive frequency of $\omega_{\mu w}/2\pi = 13.3$ GHz and indicated power. The solid line is a fit to Eq. (4.32). Note the different vertical scale of each panel.
Spin Echo

Figure 4.26: Result of an experiment to measure Ramsey oscillation using sample `UCSB-SiN`. The solid line connects measured data points, the dotted line is a fit to a sine function decaying exponentially with a time constant of $T_2^* = 90$ ns.

Fig. 3 Measurement of Rabi oscillations. The measurement probability of the $|1\rangle$ state is plotted versus microwave pulse length. Pulse sequence consists of a microwave pulse of variable time, tuned to the qubit transition frequency, followed by a measurement pulse, as depicted in the inset. Note that the probability is the raw data (with no corrections) coming from our experiment, which inherently has an absolute calibration. The Rabi oscillations have fidelity of about 90%, a value reasonably close to the theoretical expectation 96% [15]. The energy decay time for this qubit is $T_1 = 600$ ns.
Aufbau – 1 Qubit

Fig. 2 (a) Schematic diagram of a phase qubit circuit and bias lines. Symbols 20 dB, RC, and CP represent 20 dB microwave attenuators, resistor-capacitor low-pass filters, and copper-powder microwave filters, respectively. The RC filters for the qubit and SQUID bias has 1 kΩ and 10 kΩ DC resistance, respectively, and a roll-off frequency ∼ 5 MHz. The 5 μH inductor is a custom made radio-frequency bias tee with no transmitting resonances below 1 GHz. (b) Photomicrograph of present phase qubit, showing small area (∼ 1 μm²) junction shunted by a parallel plate capacitor. Microwave drive line (with capacitor, not shown) comes from the left. The qubit inductor is coupled to a SQUID readout circuit in a gradiometer geometry. The flux bias lines for the qubit are symmetrically placed about the SQUID and counter-wound to inhibit flux coupling to the SQUID. The SQUID bias line exits to the right. The holes in the ground plane inhibit trapped vortices in the superconducting ground plane.
